Applications of Genetics to Cardiovascular Medicine

Pradeep Natarajan and Kiran Musunuru

Hypercholesterolemia and Coronary Artery Disease

- FH afflicts approximately 1 in 300 individuals, manifesting as severely elevated blood cholesterol levels and increased risk for early-onset myocardial infarction.

6
Failed surface presentation
LDLR degraded

However, a single pathogenic variant in the canonical FH-genes (*LDLR, APOB or PCSK9*) is identified in only **15–50%** of phenotypical FH patients (classified by clinical scoring systems)

in the early 2000s, linkage and cloning analyses of families with autosomal recessive FH prioritized a large region on chromosome 1.

Ultimately, homozygous mutations in LDLRAP1 (previously known as ARH, autosomal recessive hypercholesterolemia).

LDLRAP1 encodes LDL receptor adaptor protein 1, which is required for endocytosis of the LDL receptor.

At present, over **3100** common genetic variants have been shown to be associated with LDL-C levels

PRS is constructed by summing the number of alleles from trait-affecting variants an individual has, weighted by their effect size as reported in the GWAS.

LDLR Mutations:
Patients with mutations in the LDLR gene have a more severe form of FH and may respond less effectively to statins compared to those with mutations in other genes like APOB or PCSK9.

APOB Mutations:
Statins are generally more effective in patients with APOB mutations compared to those with LDLR mutations.

PCSK9 Mutations:
Patients with gain-of-function mutations in PCSK9 may also have a different response to statins. While statins can still lower LDL cholesterol levels, these patients may require additional therapies, such as PCSK9 inhibitors, for optimal management due to their unique genetic profile.

For patients who do not respond adequately to statins due to their genetic makeup, other medications such as **ezetimibe or PCSK9 inhibitors** may be recommended.

- This mutation was first identified in Chinese patients and this homozygous mutation is a new genetic type of FH.

- This is the first time that WES was used in Chinese FH patients.

- They detected a novel genetic type *of LDLR* homozygous mutation.

- WES is powerful tools to identify specific FH families with potentially pathogenic gene mutations.

Metabolic Syndrome and Coronary Artery Disease

In 2007, linkage analysis of an extended family of Iranian ancestry with premature CAD and features of the metabolic syndrome resulted in the identification of a causal missense variant in LRP6.

Whole exome sequencing and focused analysis within the prioritized region identified a perfectly co-segregating missense variant in DYRK1B in all three families.

Screening of morbidly obese individuals of European descent with CAD and multiple metabolic phenotypes identified a family with co-segregation of a different missense variant in DYRK1B

- In 2007, researchers studied a **large Iranian family** with early coronary artery disease (CAD) and metabolic syndrome.
- They found a specific genetic change (missense variant) in the **LRP6 gene** that disrupted a key signaling pathway called **Wnt signaling**.

LRP6 Mutation in a Family with Early Coronary Disease and Metabolic Risk Factors

Arya Mani,[1*] Jayaram Radhakrishnan,[1] He Wang,[2] Alaleh Mani,[3] Mohammad-Ali Mani,[4] Carol Nelson-Williams,[1] Khary S. Carew,[1] Shrikant Mane,[1] Hossein Najmabadi,[5] Dan Wu,[2] Richard P. Lifton[1*]

Coronary artery disease (CAD) is the leading cause of death worldwide and is commonly caused by a constellation of risk factors called the metabolic syndrome. We characterized a family with autosomal dominant early CAD, features of the metabolic syndrome (hyperlipidemia, hypertension, and diabetes), and osteoporosis. These traits showed genetic linkage to a short segment of chromosome 12p, in which we identified a missense mutation in *LRP6*, which encodes a co-receptor in the Wnt signaling pathway. The mutation, which substitutes cysteine for arginine at a highly conserved residue of an epidermal growth factor–like domain, impairs Wnt signaling in vitro. These results link a single gene defect in Wnt signaling to CAD and multiple cardiovascular risk factors.

- They used linkage analysis to narrow down a specific area on **chromosome 19** that was linked to these conditions.
- By performing whole exome sequencing in this region, they discovered another missense variant in the **DYRK1B gene** that was consistently found in all three families.

These findings indicate a role for *DYRK1B* in adipogenesis and glucose homeostasis and associate its altered function with an inherited form of the metabolic syndrome.

Case-Control and Population-Based Studies

- A GWAS (Genome-Wide Association Study) is a research approach used to identify genetic variations across the entire genome that may be associated with a particular disease or trait.

- Scanning the genome of large groups
- High-throughput technologies (like SNP arrays or sequencing) to
- For cardiovascular diseases: lipid metabolism, blood pressure regulation, inflammation, or the structure and function of the vascular system.

THERAPEUTIC RESPONSE PREDICTION

- Genetic variants that change protein activity can help predict how effective drugs will be before they are developed.

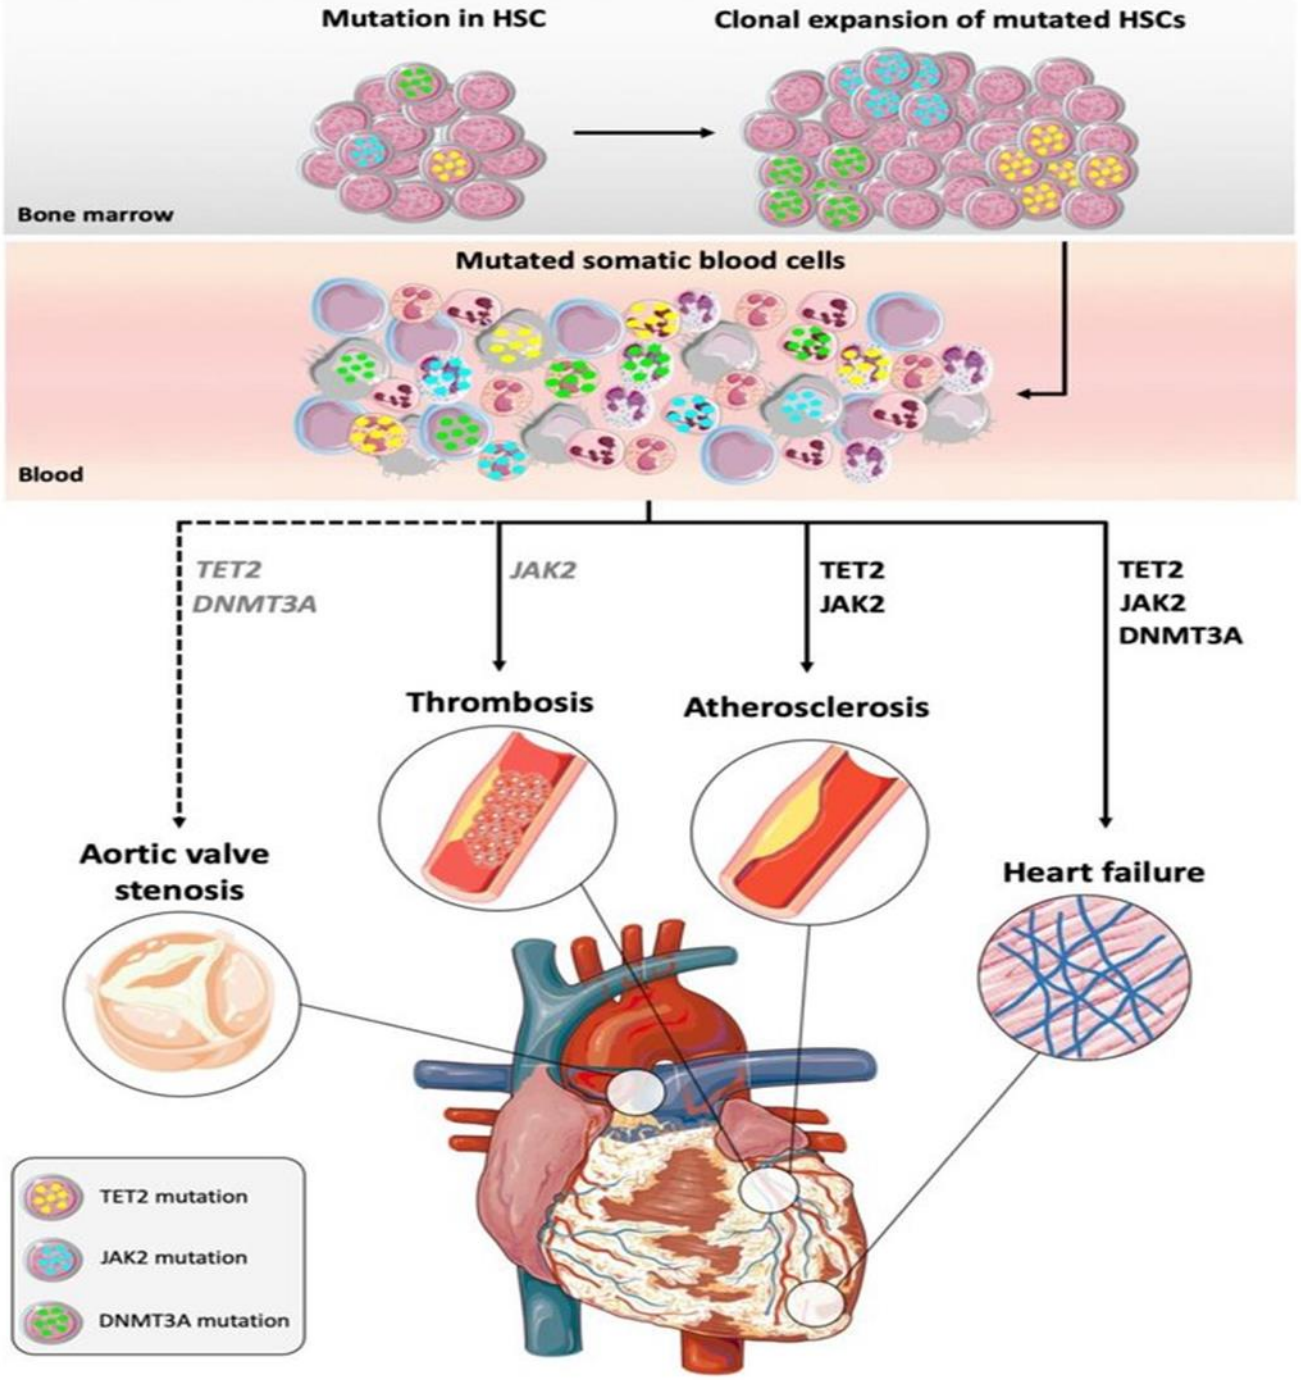
PCSK9

APOC3

CYP2C19

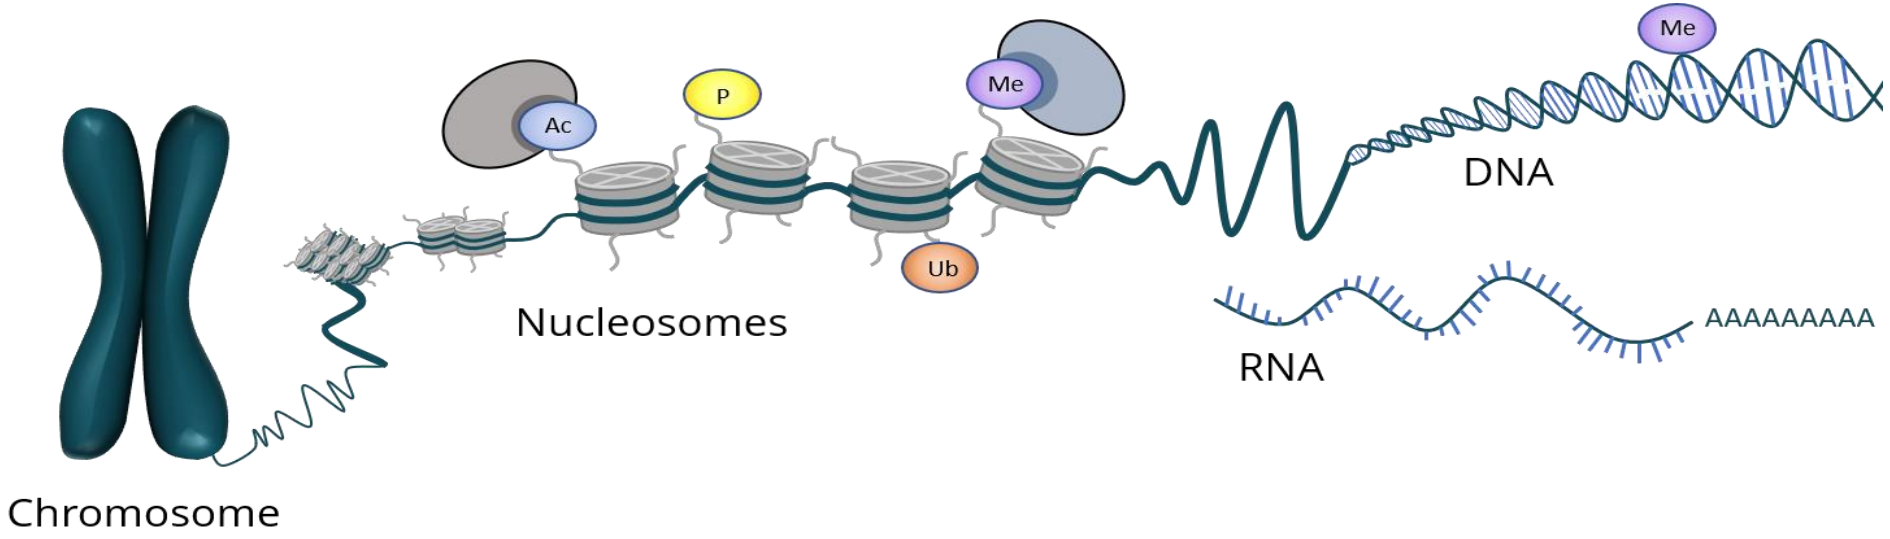
Somatic Genomics

- Age is a major risk factor for coronary artery disease (CAD), but its specific contributors are not fully understood.
- Many adults over 70 have clonal hematopoiesis of indeterminate potential (CHIP), which is linked to both cancer and CAD.
- Studies suggest that inhibiting the NLRP3 **inflammasome** may better reduce atherosclerosis in those with CHIP, indicating that targeting inflammation could be particularly beneficial for these individuals.



Epigenetics

- Epigenetics may play a role in CAD because environmental factors that cause changes in DNA methylation and histone acetylation are linked to CAD risk and advanced atherosclerosis.
- For instance, higher levels of **histone deacetylase 3 and 9** have been found in areas prone to plaque buildup, and inflammation in atherosclerotic plaques.
- Recent studies identified 52 specific **DNA methylation** sites related to CAD risk, with two showing a causal link.
- Additionally, certain genetic variants affect genes involved in CAD, such as ITGA6 and **long noncoding RNA**s (lncRNAs). These lncRNAs, like ANRIL, may influence atherosclerosis development and progression.



Single-cell RNA sequencing

- Single-cell RNA sequencing (scRNA-seq) is a valuable technique for studying atherosclerosis by analyzing individual cells in plaques.
- It provides detailed insights into the unique gene expression profiles of various cell types, revealing new populations like activated macrophages and "fibromyocytes."
- This technology helps researchers understand the roles of these cells in disease progression and how specific genes influence atherosclerosis.
- Overall, scRNA-seq enhances our understanding of cellular interactions and potential therapeutic targets in atherosclerosis.

Therapeutically Targeting the Genome

- Human genetics has inspired new therapeutic strategies that target mRNAs instead of just proteins.
- Key approaches include antisense oligonucleotides (ASOs) and RNA interference (RNAi), both of which inhibit mRNA translation.
- Gene therapy can replace deficient gene products or enhance protective genes, while emerging gene editing techniques aim to directly correct harmful genetic variants.
